## Abstract

Hepatocellular carcinoma (HCC) is the most prevalent liver cancer, accounting for more than 80% of all liver cancers worldwide. HCC is the fourth leading cause of cancer-related death in 2018. Globally, nearly 800,000 new cases of HCC have been diagnosed each year. The development of HCC results from the dysfunction of a multistep biological mechanism in liver where healthy hepatocytes become malignant. Several factors like regulation of oxidative stress, genetic and epigenetic alterations, inflammation, and immunity are involved in the development of HCC. Hepatitis B and C, alcohol- and drug-induced steatohepatitis, aflatoxins, and carcinogens such as polyvinyl chloride, polychlorinated biphenyls, pyrethrins, chlordane, and dithiothreitol are all major risk factors for HCC. These risk factors often affect hepatocytes to cause hepatotoxicity by cholestasis, fatty liver, fibrosis, and cirrhosis leading to HCC. These risk factors modulate oxidative stress, proliferation, apoptosis, mitochondrial dysregulation, lipid metabolism, insulin resistance, and many more by regulating various signaling pathways such as P53, P73, Ras, Wnt/ $\beta$ -catenin, JAK/STAT3, Bcl-2, CDK-4, mitogen-activated protein kinase, tumor necrosis factor- $\alpha$ , and transforming growth factor- $\beta$  are involved in the development of HCC. Understanding the potential mechanisms underlying these HCC-related risk factors will aid in the development of new therapeutic strategies to reduce HCC-related morbidity and mortality.

**Keywords:** Hepatocellular carcinoma; hepatitis B virus; hepatitis C virus; nonalcoholic fatty liver disease; nonalcoholic steatohepatitis

## Abbreviation

EMT	epithelial-to-mesenchymal <i>trans</i> -differentiation
HBx	hepatitis B X protein
HBV	hepatitis B virus
HCV	hepatitis C virus

<b>HSCs</b>	hepatic stellate cells
<b>MAPK1</b>	mitogen-activated protein kinase 1
<b>NAFLD</b>	nonalcoholic fatty liver disease
<b>NASH</b>	nonalcoholic steatohepatitis
<b>NF-<math>\kappa</math>B</b>	nuclear factor- $\kappa$ B
<b>PKR</b>	protein kinase R
<b>TERT</b>	telomerase reverse transcriptase
<b>TGF</b>	transforming growth factor
<b>TNF-<math>\alpha</math></b>	tumor necrosis factor- $\alpha$

---

## Introduction

---

Hepatocellular carcinoma (HCC) is the most prevalent liver cancer, accounting for over 80% of all liver cancers worldwide. HCC was the fourth leading cause of cancer-related death in 2018 [1]. HCC incidence and mortality rates have been rising in recent decades, with about 800,000 new cases identified each year [2]. It has a wide geographic range, with many cases occurring in developing countries such as sub-Saharan Africa and Asia [3]. HCC is a complex disease that develops due to underlying liver dysfunction caused by a multistep biological mechanism in which healthy hepatocytes become malignant. The development of HCC is influenced by oxidative stress, genetic and epigenetic changes, inflammation, and immunity [4]. Further, HCC has been linked to a number of other environmental risk factors.

Viral infections such as hepatitis B virus (HBV) and hepatitis C virus (HCV) are the most common causes of persistent liver inflammation [5]. This inflammation eventually weakens the liver immune system, contributing to the severity of the necrotic-inflammatory injury, the formation of liver fibrosis, and the progression of the disease to HCC [6]. Aflatoxin-contaminated food consumption, nonalcoholic steatohepatitis (NASH), environmental toxic intake, and exposure to additional chemical carcinogens (polyvinylchloride, trichloroethylene, and so on) are all significant risk factors (Fig. 3.1). Recent reports suggested that the metabolic syndrome, including diabetes as well obesity, raises the risk of HCC [7]. Chronic inflammation—induced hepatocyte necrosis, decreased regeneration potential, and fibrotic deposition are common early signs of HCC progression. Understanding the basic mechanisms underlying its emergence and progression may aid in its prevention. Disparities in HCC treatment can only be avoided if the disease is detected and treated early [8].

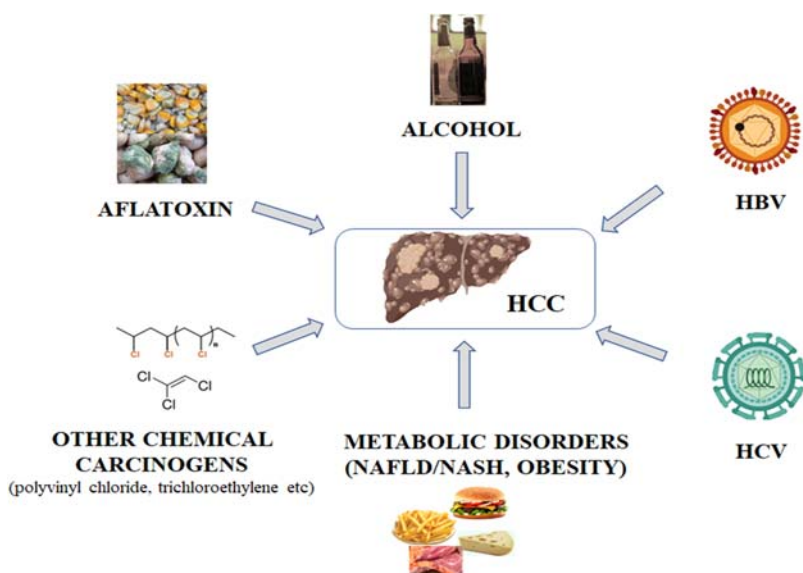

---

## Risk factors

---

### Viral hepatitis B and C

Chronic HBV and HCV infections are responsible for more than 80% of all HCC cases worldwide. Host factors, environmental factors, and hepatitis viruses all play a role in the development of HCC [9]. HCC cases are thought to be significantly higher in eastern Asia and sub-Saharan Africa, where HBV infection is thought to be widespread [10]. Increases in HCV infection, longer alcoholic intake, and nonalcoholic fatty liver disease (NAFLD) all

**FIGURE 3.1** A number of risk factors contribute to the development of hepatocellular carcinoma.

contribute to a higher prevalence of HCC in Western countries. HCC develops in 2%–5% of cirrhotic patients with chronic HBV or HCV infection each year [1,11].

People who have been infected with HBV for a long time have a 5–100-fold increased risk of developing HCC [12]. Although HBV infection is asymptomatic in the early stages, 15%–40% of chronic HBV patients develop cirrhosis or cirrhosis-related complications over the course of their lives [13]. HBV DNA levels are higher in patients with chronic HBV infection, which is one of the major risk factors for the development of HCC. The most effective treatments focused on lowering HBV DNA levels rather than eradicating the infection completely [14].

## Alcohol

Worldwide, alcohol consumption is the second leading cause of HCC [15]. In developed countries, particularly the United States and Europe, alcohol consumption is higher, and it is one of the leading causes of HCC in these regions [16]. Excessive alcohol consumption increased the risk of cirrhosis and HCC in a linear dose–response relationship [17]. When alcohol consumption exceeds 80 g a day for more than 10 years, the risk of HCC is expected to rise by five to seven folds [18]. Multiple studies have shown that alcohol use, either alone or in combination with HBV, HCV, and diabetes, causes HCC [19].

## NAFLD-/NASH-induced HCC

NAFLD is the most common liver disease, accounting for nearly 25% of all liver diseases worldwide [1]. NAFLD is characterized by a number of liver diseases, including

triglyceride accumulation, apoptosis, inflammation, and fibrosis, collectively known as NASH [20]. NAFLD has emerged as a major risk factor for HCC in recent years, with studies indicating that it can increase the risk of HCC by up to 2.6 fold. Apart from NASH and NAFLD caused by cirrhosis, noncirrhotic NASH or benign steatosis has also been linked to HCC development [21].

Patients with NAFLD can develop a variety of liver diseases, ranging from simple steatosis to liver cell injury, as a result of triglycerides accumulation in their livers. NASH is the first stage of the inflammatory phase of NAFLD, which occurs in people who drink little or no alcohol [22]. The metabolic syndrome is key to the link between NASH and HCC. NASH causes inflammation, hepatocellular injury, and fibrosis, all of which raise the risk of HCC, which has a high mortality rate. NAFLD is the hepatic manifestation of metabolic syndrome and is associated with obesity and diabetes [23]. Metabolic syndrome is associated with the lipid accumulation in the liver. Excessive lipid accumulation leads to oxidative stress and mitochondrial dysfunction. Changes in lipid metabolism, changes in the immune system, and changes in growth and development pathways are all procarcinogenic processes caused by mitochondrial damage [24].

## Aflatoxins

Aflatoxins are mycotoxins with a strong hepatocarcinogenic effect that can be found in a variety of cereals and oilseeds [25]. About 25% of the world's crops are thought to be contaminated with aflatoxins. In Western countries, exposure to aflatoxins is minimal, while in some West African countries, due to insufficient postharvest processing, more than 90% of the general population is exposed to aflatoxins [26]. Aflatoxin exposure is thought to be one of the causes of HCC, as evidenced by the presence of multiple aflatoxin contaminations in areas where HCC is prevalent [27]. The toxic metabolites of aflatoxin enter the human system through polluted animal and plant products eaten as food, particularly grains. There are nearly 18 aflatoxins identified, but 4 of them, AFB 1, AFB 2, AFG 1, and AFG 2, have been proven to carcinogenic in both animals and humans [28].

## Other chemical toxicants

Exposure to hazardous chemicals at workplace is also a possible risk factor for HCC [29]. Workers are frequently exposed to a broad range of hazardous chemical agents as a result of a variety of workplace practices. The liver is the primary detoxifying organ, and it is responsible for all xenobiotics that enter the body. The liver is the main target organ because it is the primary site for a number of metabolic and excretory processes. Hepatotoxicity is caused by toxic chemicals carcinogens such as polyvinyl chloride, polychlorinated biphenyls, pyrethrins, chlordane, and dithiothreitol, which cause cholestatic injury, hepatocellular damage, fatty liver, fibrosis, and cirrhosis, as well as malignancies such as HCC [30]. Trichloroethylene, arsenic, cadmium, lead, thallium, and nickel, among other toxic metals found in contaminated ground water, have negative effects on the liver [31,32].

## Mechanisms of action

### Hepatitis B virus infection

HBV is a DNA-coated Hepadnaviridae virus. HBV is a reverse-transcribed, partially double-stranded DNA virus that is noncytotoxic. The structural core protein (HBc), envelope proteins, reverse transcriptase, and an oncoprotein called the regulatory hepatitis B X protein (HBx) are all encoded by this viral genome [33,34]. These proteins play a crucial role in the progression of HCC. The size of the envelop protein is divided into three parts: small (S), medium (M), and large (L). To complete the replication process, the N-terminal extensions of the M and L types of envelop proteins interact with the endoplasmic reticulum (ER) membrane. Noncircularized HBV genomes have been confirmed to integrate into the hepatocellular genome after previously being thought to be unrelated to the virus's life cycle [35].

HBV can trigger HCC in a number of ways, including oxidative stress and viral proteins [36]. As a result of the incorporation of HBV DNA into the host genome, HBx mediates a specific mechanism that alters the expression of endogenous genes or promotes chromosomal instability [37]. Physical interactions between the virus and the ER trigger HBV-induced hepatocarcinogenesis by aggravating ER stress and ultimately triggering oxidative stress, which activates multiple signaling pathways, inducing mutations and triggering hepatic stellate cells (HSCs) [38]. Microdeletions of cancer-relevant genes such as telomerase reverse transcriptase (TERT) and mitogen-activated protein kinase 1 (MAPK1) from host DNA are frequently associated with HBV genome integration [39]. SRC (Proto-oncogene tyrosine-protein kinase Src) tyrosine kinases, Ras, Raf (rapidly accelerated fibrosarcoma), MAPK, extracellular signal-regulated protein kinase, JNK (Janus kinase), and other growth-control genes are all affected by HBx transcriptional activation activity [40]. Finally, HBx binds to and inactivates the tumor suppressor gene p53, resulting in uncontrolled cellular proliferation, compromised cell survival, and DNA-damage checkpoints (Fig. 3.2) [41].

FIGURE 3.2 Mechanism of HBV involved in progression of HCC. *HBV*, Hepatitis B virus; *HCC*, hepatocellular carcinoma.

At the molecular and cellular levels, the HBx has a variety of functions, including disrupting apoptosis in hepatocytes and modulating DNA-binding specificity via transcriptional regulation of the p53 tumor suppressor gene, which is important in the progression of HCC [42,43]. The HBx is also involved in cell cycle progression and cellular signaling. The HBx interacts with a variety of host factors to activate the Ras–Raf–MAPK pathway, Src-dependent pathway, phosphatidylinositol 3-kinases (PI3K)–Akt pathway, nuclear factor- $\kappa$ B (NF- $\kappa$ B)/STAT-3 pathway, and wnt/-catenin pathway to maintain its genetic stability [44]. HBx alters the methylation profiles of oncogenes and tumor suppressor genes, as well as the acetylation of histone proteins in tumor-related genes and changes in many microRNAs, resulting in epigenetic changes [45].

## Hepatitis C virus infection

HCV infection causes one-third of all HCC cases worldwide, making it a global health concern. The onset of cirrhosis increases the risk of HCC cases from 1% to 8% in patients with chronic HCV infection [46]. HCC caused by HCV infection is a common sign that a liver transplant is necessary [47].

HCV is a single-stranded RNA virus that belongs to the Hepacivirus family and is noncytotoxic. After translation, this RNA encodes a 3000 amino acid polyprotein that is degraded into structural (S) and nonstructural (NS) proteins by proteolysis. The core protein, the envelope E1 and E2 glycoproteins, and the p7 protein are structural proteins that make up the viral particle and are involved in viral morphology and host cell entry [48]. Nonstructural proteins NS1, NS2, NS3, NS4A/B, and NS5A/B are involved in genome replication, particle assembly, and infection [49]. HBV infection, obesity, insulin resistance, and steatohepatitis all contribute to the development of HCV-related HCC [9]. Immune-mediated chronic inflammation is thought to aid in the development of HCC during HCV infection. Interfering with a variety of cell pathways that control energy metabolism, cell proliferation, and apoptosis can also cause HCC [50]. HCV can cause double-stranded DNA breaks, which can lead to mutations in genes such as BCL-6, TP53, immunoglobulin genes, and  $\beta$ -catenin [51].

HCV infection is a leading cause of HCC, and it is mediated by viral-induced factors as well as the host's immune response. Interactions of structural and nonstructural proteins with various host cellular proteins alter hepatocytes slightly (Fig. 3.3). HCV replicates in the cytoplasm of hepatocytes after integrating its genome into the host DNA. HCV-associated HCC is caused by virus-induced, often indirect, deregulation of host cellular processes such as liver cell proliferation and steatosis, oxidative stress and inflammation inducing mutations and genome instability, mitochondrial dysregulation, and generation of free radicals [52].

HCV may also cause HCC in the host cell by interfering with cellular regulatory pathways such as insulin resistance, proliferation, epithelial-to-mesenchymal *trans*-differentiation (EMT), apoptosis, DNA repair, and oxidative stress [49]. HCV core proteins, as well as various NS proteins, may all play a role in HCV-related HCC development and progression. HCV viral proteins can cause HCC by activating signaling pathways that promote cell division and growth, and also by inhibiting tumor suppressor genes [53].

The HCV core protein can cause lipogenesis and an increase in reactive oxygen species (ROS) production, which can lead to mitochondrial oxidation and oxidative stress metabolism

**FIGURE 3.3** Mechanism of HCV involved in the progression of HCC. HCC, Hepatocellular carcinoma; HCV, hepatitis C virus.

problems [54]. HCV core protein inhibits tumor suppressor genes like p53 and retinoblastoma protein. The loss of p53 and retinoblastoma work together to cause a higher degree of HCC. P73 and P21, two tumor suppressor proteins, interact with core protein as well as tumor necrosis factor- $\alpha$  (TNF) signaling or a Bcl-2 family member that regulates apoptosis [55]. The HCV protein core also affects cell cycle signaling pathways by increasing cyclin E/Cdk2 levels, as well as RAF/MAPK, which promotes cell proliferation and development by inducing Wnt/-catenin and transforming growth factor (TGF)- $\beta$  signaling pathways [56–58]. All of these pathways point to a role for this protein core in reducing apoptosis and promoting cell proliferation as HCC progresses. The E1/E2 structural proteins inhibit dsRNA protein kinase (PKR) and promote cell proliferation and survival by inhibiting NK (Natural Killer) or T-cell activation and the MAPK/extracellular signal regulation via the inclusion of transcription factor ATF-2 [59].

The nonstructural protein component of HCV aids in the growth of HCC through inducing TGF- $\beta$  and activating HSCs. The TP53, TERT, and  $\beta$ -catenin genes are commonly mutated in HCC. Mutations of these genes impend telomere maintenance, which ultimately leads to increased oxidative stress. Nonstructural protein NS2 induces expression of cyclin E by triggering cyclin D/CDK4 and also play significant role in the process of apoptosis by intrusion with p53 pathway [60]. NS3, a nonstructural protein, regulates a number of signaling pathways that have the potential to transform cells. In addition, it interacts with protein kinase A and prevents it from translocating to the nucleus. It involves preventing immune surveillance by inhibiting type-1 interferon induction mediated by interferon response factor (IRF-3). Further, by targeting adaptor molecules in the TLR3 and RIG-1 signal pathways, NS3/4A inhibits IRF-3 transcription factor activation and promotes cell proliferation [61].

The other, nonstructural protein, NS5A is a transcription factor activator involved in cell proliferation and apoptosis inhibition via the cell cycle, Bcl-2, PI3K, Wnt/ $\beta$ -catenin signaling, and mTOR (mammalian target of rapamycin) signaling [62]. It disrupts the PKR-p38 signaling pathway, resulting in abnormal mitosis, inhibits TGF signaling, preventing SMAD (Mothers against decapentaplegic (MAD) homolog) proteins nuclear translocation, and inhibits TNF-mediated apoptosis [63]. It affects the EMT pathway and aids in the conversion of epithelial cells to mesenchymal stem cells. TGF and NS5A work together to activate stellate cells, which leads to fibrosis. NS5B relocates Rb back into the cytoplasm after binding with it. E2F sensitive genes were activated to induce cell cycle progression due to the proteasomal degradation [64] (Fig. 3.4).

## Alcohol

Excessive alcohol consumption activates Kupffer cells by stimulating monocytes. Activated Kupffer cells release chemokines and cytokines such as interleukin-6 (IL-6), TNF, and prostaglandin E2. Chronic hepatocyte regeneration–destruction, HSC activation, cirrhosis, caused by these cytotoxic effects, eventually lead to HCC [65]. Cirrhosis is one of the most important factors in the progression of HCC. Alcohol, on the other hand, can cause HCC through oxidative stress, inflammation, and endotoxemia. Acetaldehyde, which is produced from ethanol by the enzyme alcohol-dehydrogenase (ADH), disrupts the redox balance in mitochondria and inhibits hepatocyte-oxidation, leading to an increase in fatty acid oxidation and lipogenesis, which promotes steatosis and inflammation [66]. Acetaldehyde is a naturally occurring highly toxic and carcinogenic substance.

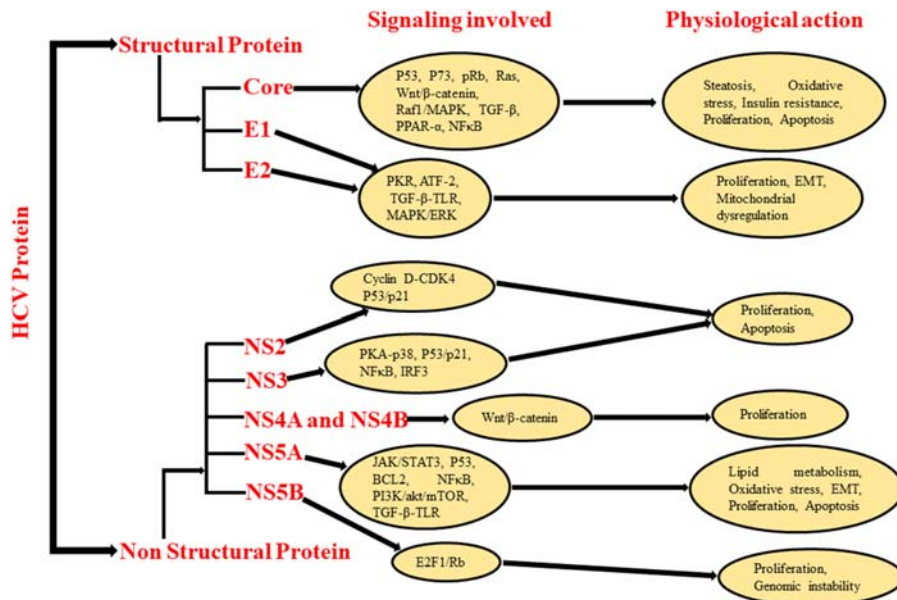

FIGURE 3.4 Role of different HCV proteins in the progression of HCC. HCC, Hepatocellular carcinoma; HCV, hepatitis C virus.

ADH-positive tumor cells have a high capacity for alcohol oxidation but a limited ability to remove acetaldehyde [67]. Excessive alcohol consumption activates cytochrome CYP2E1, which boosts acetaldehyde production in the liver. Accumulation of acetaldehyde causes mitochondrial dysregulation, which leads to an accumulation of ROS, which contributes to alcohol-induced oxidative stress in hepatocytes. Furthermore, the aggregation of intracytoplasmic lipid droplets in alcohol-induced steatosis may make hepatocytes more vulnerable to toxic effects [68]. Enzymatic inactivation, lipid peroxidation, and DNA mutations may all result in cellular damage and inhibit apoptosis when there is an excess of ROS produced in combination with the accumulation of injured proteins [18]. As levels of ROS increase, lipid peroxidation products such as malondialdehyde and 4-hydroxy-2-nonenal are produced, causing a mutation in the p53 gene at codon 249, which prevents cell apoptosis and promotes cell proliferation [69,70]. These lipid peroxidation products also result in the formation of HCC-causing mutagenic DNA adduct (Fig. 3.5).

DNA adducts such as *N*2-ethyl-20-deoxyguanosine and *N*2-propanol-20-deoxyguanosine can be formed by acetaldehyde, which is capable of initiating replication errors and alter the integrity of hepatocyte DNA [71,72]. The *O*6-methylguanosyl transferase, for example, forms adducts that weaken the process of DNA repair and can play a role in HCC [73]. Acetaldehyde may also form stable adducts with proteins, causing structural and functional changes. Furthermore, acetaldehyde destroys mitochondria, causing fatty acid oxidation to be inhibited. Acetaldehyde stimulates the synthesis of collagen in HSCs, which is a crucial step in the progression of cirrhosis and the growth of HCC. ROS are important mediators of tumor angiogenesis and metastasis, resulting in the activation of the NF- $\kappa$ B signal [74]. Iron overload and TNF- $\alpha$  from inflammatory cells also influence the production of ROS. Chronic alcohol intake also increases intestinal iron absorption and hepatic iron storage. Iron overload causes breakdown of DNA strands and mutation of p53 gene, which could cause HCC [75].

## NAFLD-/NASH-induced HCC

The pathogenic pathways involved in HCC induced by NAFLD/NASH can be linked to metabolic syndrome and obesity-induced chronic inflammation [76]. Insulin resistance

FIGURE 3.5 Alcohol-induced pathways involved in the progression of HCC. HCC, Hepatocellular carcinoma.

plays major role as one of the mediators, whether or not there is severe fibrosis or cirrhosis. Fig. 3.6 shows the interactions between NAFLD-/NASH-induced mechanisms leading to HCC. NAFLD is primarily caused due to the modulation of caloric excess by poor diet and a sedentary lifestyle [77]. Insulin resistance plays a critical role in this pathophysiological mechanism, as it leads to an increase in liver fat accumulation due to an increase in free fatty acid deposition (FFAs). The abundant amount of FFAs deposition cause lipotoxicity that promotes oxidative stress, protein misfolding and mitochondrial impairment within liver cells. ROS overproduction causes mitochondrial damage, lipid peroxidation, inflammation, and HSC activation, which leads to necrosis, cirrhosis, and HCC [78]. Insulin tolerance, lipid accumulation, apoptosis, and inflammation are all related to NAFLD pathogenesis by dysregulated ER stress in the liver (Fig. 3.6).

Metabolic stress increases ROS production and induces inflammatory cytokine release from liver cells, which triggering the JAK2/STAT (signal transducer and activator of transcription), MAPK, and PI3K signaling pathways in HCC cells by binding to their receptors [79]. TNF- $\alpha$  is promoting the progression of HCC activating hepatic progenitor cells, and IL-6 activates an oncogenic transcription factor that promotes cell proliferation and inhibits apoptosis, playing a role in the progression of NASH-related HCC [80].

FIGURE 3.6 Interactions between NAFLD-/NASH-induced mechanisms leading to HCC. HCC, Hepatocellular carcinoma; NAFLD, nonalcoholic fatty liver disease; NASH, nonalcoholic steatohepatitis.

Several hormones, including insulin and insulin-like growth factor 1 (IGF-1), play important roles in developing NAFLD-related HCC [81]. Insulin resistance and hyperinsulinemia are often responsible for this to happen. Insulin and IGF-1 activate the PI3K and MAPK pathways through a cascade of signaling by binding to their respective receptors. Both the pathways are critical in the origination and progression of HCC since they regulate proliferation and apoptosis in the cell.

Several single nucleotide polymorphisms, several microRNAs (miRNAs), and genetic instability are also encouraging NASH to HCC progression [82]. Exome-sequencing study of HCC identified key mutations in some oncogenic genes, including TERT involved in p53 and Wnt/ $\beta$ -catenin signaling pathway. It also facilitates the binding of nucleotides to the ends of eukaryotic chromosomes [83]. Epigenetic changes, such as abnormal DNA methylation, silenced DNA repairing genes, metabolism of lipids and fibrosis progression, are also key factors in NASH progression [84]. Noncoding RNAs such as miRNAs interfere with transcription and translation by suppressing gene expression. These miRNAs involved in major cell signalings, pathways, including Wnt/ $\beta$ -catenin, MAPK, TGF- $\beta$ , and PI3K/AKT/mTOR can be triggered in HCC [85].

## Aflatoxins

Aflatoxin is mainly metabolized in the liver cells [86]. As a result of aflatoxin exposure, DNA adducts form in hepatocytes, activating the mutation site of the tumor suppressor gene p53, indicating aflatoxin's direct involvement in HCC [87]. The p53 gene induces apoptosis and cell cycle arrest, which contributes to the deactivation of mutations in the p53 gene or other pathway mechanisms, which can reduce hepatocyte susceptibility to other cancer-causing agents that trigger oncogenic pathways and influence the production of HCCs [88].

Aflatoxin carcinogenicity has been linked to hepatocytes, where they are first metabolized into reactive intermediate metabolites. AFB1-exo 8,9-epoxide, the first intermediate product of AFB1 metabolism by microsomal cytochrome enzyme, is one of the most well-studied aflatoxins (CYP450). This is thought to be the most serious cause of genotoxicity. The International Agency for Research on Cancer classified the most harmful hepatic carcinogen, AFB1, as a type I human carcinogen in 1993 [89]. CYP3A4, CYP3A5, CYP3A7, and CYP1A2 are cytochrome P 450 enzymes that transform aflatoxins to AFB1 in the liver. AFB1 is gradually converted into the AFB1 form amidopyrimidine adduct, a cancer-causing agent. AFB1 metabolites interact with DNA by alkylating bases, causing cell cycle disruption and mutations in the tumor suppressor gene p53 [90]. The most common mutations in the TP53 tumor suppressor gene (AGG to AGT), which result in the substitution of arginine for serine, are transversions [91]. When AFB1 binds to DNA, it forms a promutagenic adduct called 8,9 dihydro-8-(N7-guanyl)-9-hydroxy AFB1 (AFB1-N7-Gua), which can be transformed into secondary byproducts, including an apurinic site and AFB1-form amidopyrimidine (AFB1-FABY). This adduct causes a transverse mutation from guanine (G) into thymine (T) (Fig. 3.7).

There is a direct connection between HBV and aflatoxin exposure in HCC risk [92]. Chronic HBV infection activates the cytochrome P450s enzyme, which converts inactive AFB1 to the mutagenic AFB1-8,9-epoxide, which binds to the guanine base and causes

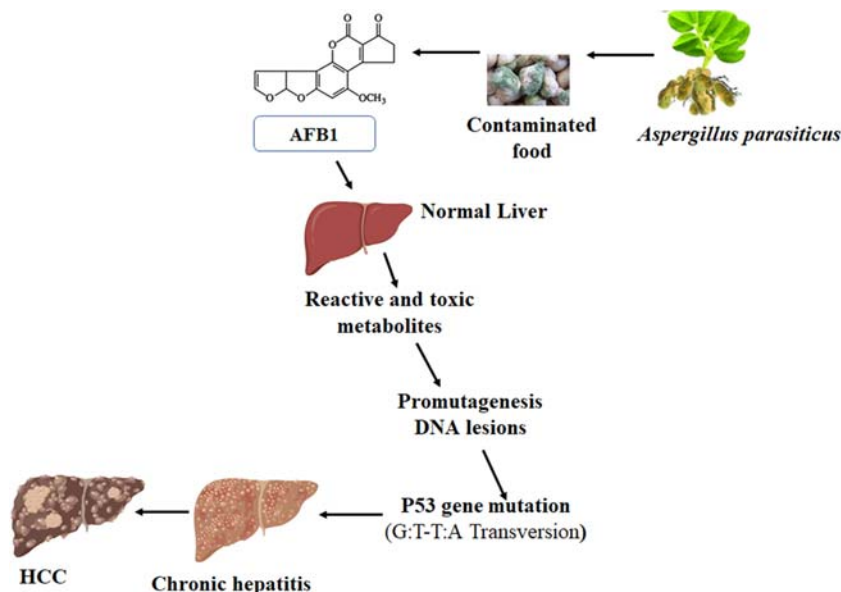

FIGURE 3.7 Interactions between aflatoxin-induced mechanisms leading to HCC. HCC, Hepatocellular carcinoma.

mutations [93]. Chronic HBV infection induces hepatic cell necrosis, which raises the risk of AFB<sub>1</sub>-induced TP53 mutations. In addition, the oncogenic HBV protein inhibits nuclear excision repair, which is responsible for removing AFB<sub>1</sub>-DNA adducts [94].

## Others

Chemical solvents (aromatic, chlorinated, toluene, dioxin, xylene, and alicyclic hydrocarbons) and trichloroethylene and perchloroethylene have been linked to exacerbating liver damage, which may contribute to the production of HCC [95]. These chemical compounds (dichlorodiphenyltrichloroethane and nitrosamines) can interact with proteins and nucleic acids and induce a cancer-causing condition in the liver. Because of the toxicity of these metabolites, they can be oxidized to form an increase in ROS output. Overproduction of ROS activates signaling pathways that promote hepatic inflammation, apoptosis, necrosis, and HCC growth. They also shorten telomeres and regulate the CYP3A1 gene, all of which have oncogenic effects [96,97].

## Conclusion

The pathogenesis of HCC is an elaborated and multitiered process that comprises diverse cellular and molecular signaling pathways. Chronic HBV and HCV infection, NAFLD/NASH, alcohol intake, aflatoxin, chemical contaminants, and genetic disorders

are all considered to raise the risk of HCC progression, making it a significant public health issue. The mechanisms underlying all of this toxicant-induced hepatic carcinogenesis are complex and vary depending on the etiologic factors. These toxic agents increase oxidative stress, inflammation, dysregulation of lipid metabolism, fibrosis, cirrhosis, and disruption of the host immune system resulted in chromosomal instability and gene expression changes. Other factors that have been related to the production of HCC include genomic methylation and miRNA expression. Furthermore, toxic metabolites formed by these toxicants are likely to function simultaneously and in concert to trigger cellular signaling, genetic, and epigenetic mechanisms that promote HCC progression. Understanding the potential mechanisms underlying these HCC-related risk factors will aid in the development of novel therapeutic strategies to reduce HCC-related morbidity and mortality. Further studies on the mechanisms and metabolism of carcinogenic agents that mediate the oncogenic process are needed.

VOLUME 1

# Theranostics and Precision Medicine for the Management of Hepatocellular Carcinoma

## Biology and Pathophysiology

### Edited by

**Ganji Purnachandra Nagaraju**, School of Medicine, Division of Hematology and Oncology, University of Alabama, Birmingham, AL, United States

**Sujatha Peela**, Department of Biotechnology, Dr. BR Ambedkar University, Srikakulam, AP, India

*Theranostics and Precision Medicine for the Management of Hepatocellular Carcinoma* provides comprehensive information about ongoing research as well as clinical data about liver cancer. It presents detailed descriptions about diagnostics and therapeutic options for easy understanding, with a focus on precision medicine approaches to improve treatment outcomes.

The first volume, **Biology and Pathophysiology**, discusses topics, such as tumor microenvironment in hepatocellular carcinoma (HCC), endoplasmic reticulum stress and unfolded protein response, effects of cirrhosis and hepatitis on the prognosis of HCC, mitochondrial metabolism, next-generation sequencing, and telomerase. In addition, it discusses exosome's role in HCC progression and metastasis, and chemokines.

It is a valuable resource for cancer researchers, oncologists, graduate students, hepatologists, and members of biomedical research who need to understand more about liver cancer to apply in their research work or clinical setting.

### Key features

- Provides updated literature review and detailed understanding of liver cancer tumor biology
- Discusses the abnormal changes in the liver caused, result from, or are associated with HCC with a holistic view
- Presents the content with fully colored images and summarizing tables for easy understanding of complex topics
